Dramatic Declines in North Atlantic Diadromous Fishes

KARIN E. LIMBURG AND JOHN R. WALDMAN

We examined the status of diadromous (migratory between saltwater and freshwater) fishes within the North Atlantic basin, a region of pronounced declines in fisheries for many obligate marine species. Data on these 24 diadromous (22 anadromous, 2 catadromous) species are sparse, except for a few high-value forms. For 35 time series, relative abundances had dropped to less than 98% of historic levels in 13, and to less than 90% in an additional 11. Most reached their lowest levels near the end of the observation period. Many populations persist at sharply reduced levels, but all species had suffered population extirpations, and many species are now classified as threatened or endangered. Habitat loss (especially damming), overfishing, pollution, and, increasingly, climate change, nonnative species, and aquaculture contributed to declines in this group. For those diadromous fishes for which data exist, we show that populations have declined dramatically from original baselines. We also discuss the consequences of these changes in terms of lost ecosystem services.

Keywords: diadromous fishes, overfishing, dams and other threats, habitat loss, shifting baselines

Dramatic Declines in North Atlantic Diadromous Fishes

We examined the status of diadromous (migratory between saltwater and freshwater) fishes within the North Atlantic basin, a region of pronounced declines in fisheries for many obligate marine species. Data on these 24 diadromous (22 anadromous, 2 catadromous) species are sparse, except for a few high-value forms. For 35 time series, relative abundances had dropped to less than 98% of historic levels in 13, and to less than 90% in an additional 11. Most reached their lowest levels near the end of the observation period. Many populations persist at sharply reduced levels, but all species had suffered population extirpations, and many species are now classified as threatened or endangered. Habitat loss (especially damming), overfishing, pollution, and, increasingly, climate change, nonnative species, and aquaculture contributed to declines in this group. For those diadromous fishes for which data exist, we show that populations have declined dramatically from original baselines. We also discuss the consequences of these changes in terms of lost ecosystem services.

or properties that support human well-being either directly or indirectly. In this paradigm, diadromous fishes have four special roles, although we will show that their importance in these functions has diminished greatly as a result of their population declines. First, provisioning of protein and other products is a primary ecosystem service of diadromous fishes because of their (historic) vast abundances, the high predictability of these runs, and the ease of their capture as they aggregate near or on their spawning grounds (Bolster 2008). Second, these fishes link continental and marine ecosystems, transporting embodied productivity from one to the other. Semelparous anadromous fishes (those that spawn once and then die) may act as keystone species (Willson and Halupka 1995): They have a major impact in their ecological communities because their carcasses are consumed directly by wildlife or stream infauna, or they decompose and release their nutrients to the water or riparian zones. Garman (1992) estimated that the nontidal James River, in Virginia, may have received annual biomass input from anadromous alosines of 1.55 kilograms (kg) per hectare (ha) (representing 3.6 million individuals in the run, with 70% mortality) before dams blocked their movements. Garman (1992) determined mean decomposition rates on the order of 10 days. These subsidies of “marine-derived nutrients” often serve as critical additions of energy and nutrients that fuel food webs well beyond the streams in which they died (Gende et al. 2002).

A third ecosystem service generated by diadromous species is the support of marine food chains through the addition of fish that emigrate from natal rivers to the sea, again transporting energy and nutrients, but in the reverse direction. At northern temperate latitudes, these fluxes are composed mainly of young fishes emigrating seaward. Nineteenth-century reports noted that the voluminous outpourings of young anadromous fishes provided important forage for marine species such as cod, Gadus morhua, tightly coupling inland production to coastal food webs (Stevenson 1899); today, such continental-marine linkages are broken to a large extent in the North Atlantic basin. This coupling also enabled fishers to harvest marine predators closer to shore without having to venture onto the high seas (Stevenson 1899).

Finally, diadromous species have played important roles for both indigenous and nonindigenous peoples. Because these fishes could supply great amounts of food after long periods with little to eat, they enjoyed high cultural status. For many coastal Native American communities, Atlantic sturgeon (Acipenser oxyrinchus), American eel (Anguilla rostrata), and other diadromous fishes had enormous practical and totemic importance (Bolster 2008). In modern American society, coastal communities still celebrate the return of American shad (Alosa sapidissima), hickory shad (Alosa mediocris), river herring (alewife, Alosa pseudoharengus, and blueback herring, Alosa aestivalis) (Waldman 2003), although these runs, and celebrations thereof, have diminished greatly.

**Metrics of change**

We synthesized information on the current status of North Atlantic diadromous fishes using these metrics: the number of original populations versus extant populations (table 1), temporal changes in population abundances or harvests (table 2, figure 1), and official conservation status (table 1). We identified 24 diadromous fishes in the North Atlantic. Of these, 12 are restricted to North America, 9 to Europe and Africa, and 3 are common to both shores. Each coast has only one strongly catadromous species, American eel and European eel (Anguilla anguilla). Information about the survival status of populations of diadromous fishes was obtained from the broadest and most recent sources available. The conservation status listed also was from the broadest possible listing identified.

Time-series data sets were collected mostly from published literature; two sets (European eel recruitment in Swedish rivers, and Atlantic salmon [Salmo salar] catches in the River Dee) were obtained from scientists in their respective fields of expertise (see the acknowledgments). Because few species have long time series of fisheries-independent data, catch statistics were the most commonly found time series. While fishery data are often subject to biases due to factors such as markets, fads, and misreporting (Ocean Studies Board 2000), in general, the species in our survey were in demand throughout most of the periods of observation.

We analyzed the time series in two ways. First, because of the variety of response variables (abundances, tons, catches per unit effort, recruitment indices), as well as the differences in absolute magnitudes of the variables, we normalized the time series so that the maximum value equals one and the minimum equals zero. These transformed data were then plotted (figure 1) for visual comparisons of trends. Second, because of the uncertainty about the meaning of individual data points (i.e., a peak in a time series in a particular year probably does not correspond to a peak in abundance or even to peak catch per unit effort expended), the untransformed data were smoothed by running averages corresponding to a particular species’ generation time, thereby lessening the importance of individual points and emphasizing the trends over the time frame of the data. The slopes of the log transformation of these smoothed time series were computed and used to calculate the percentage change in relative abundance over the period of observation (table 2).

We had an especially rich and long set of American shad landings from the Atlantic States Marine Fisheries Commission (ASMFC 2007) that could be examined for evidence of multiple shifting baselines. These were normalized to the number of river kilometers available for spawning within each river system along the eastern US coast (ASMFC 2007).

**Numbers of populations**

For many species, data on historical and present numbers of populations are deficient; the availability of information appears positively associated with their commercial importance. Of the 14 anadromous species for which comparisons

---

**Articles**
could be made, all have reduced numbers of populations (table 1). Strongly managed North American fishes such as Atlantic sturgeon, shorthose sturgeon (*Acipenser brevirostrum*), and striped bass (*Morone saxatilis*) had lost few populations. Where data allow cross-continental comparisons, Atlantic salmon in Europe have suffered relatively fewer population extirpations (13%) than in North America (33%). Alosine herrings have lost moderate numbers of populations on both sides of the Atlantic, but as much as nearly half for American shad and allis shad (*Alosa alosa*). Anadromous whitefishes

D, decline; E, extirpated; I, increase.

Note: Slopes were calculated from normalized data that had been smoothed with running averages corresponding to generation times, and then log-transformed. Generation times: alosines, salmons, and brown trout, 4 years; smelt, 2 years; striped bass, 6 years; lampreys, 9 years; eels, 10 years; sturgeons, 15 years. Slopes with an asterisk (*) indicate that they were calculated after a clear peak or nadir (e.g., after a “fishing up” period or following a collapse and subsequent recovery). Percentage increase or decrease is calculated with the fitted slope, and include the most recent years in the time series. Type of record was catch for all species except Alosa alosa (fish passage), Anguilla anguilla (recruitment index), and lamprey (fishery).

Although some anadromous species have suffered dramatic declines, the predominant pattern among these fish populations, regardless of the difference between maximum and recent values or the decline trajectories, is a general decline. Although many anadromous species continue to produce eggs, the futurity of these species is in question. Many anadromous species exhibit profound changes that are often dramatic. For example, the population of American shad in the Potomac River decreased from 32 million in 1967 to 32,000 in 1997 (Wheaton 1997). The Potomac could produce more than 22 million shad (3 kg in weight and 0.9 meters in length, on average) “in a good year” (Tilp 1978); today, only a minor recreational fishery persists in Nova Scotia and a few small fisheries remain in France’s Gironde River (Williot et al. 2002).

Although some anadromous species have suffered dramatic declines, the predominant pattern among these fish populations, regardless of the difference between maximum and recent values or the decline trajectories, is a general decline. Although many anadromous species continue to produce eggs, the futurity of these species is in question. Many anadromous species exhibit profound changes that are often dramatic. For example, the population of American shad in the Potomac River decreased from 32 million in 1967 to 32,000 in 1997 (Wheaton 1997). The Potomac could produce more than 22 million shad (3 kg in weight and 0.9 meters in length, on average) “in a good year” (Tilp 1978); today, only a minor recreational fishery persists in Nova Scotia and a few small fisheries remain in France’s Gironde River (Williot et al. 2002).
ones are even greater than what has been observed in many obligate marine species. Thirteen of the 35 time series in table 2 had declined by more than 98%; another 11 had declined by more than 90%. The few exceptions include the coastal migratory stock of striped bass, northern European populations of Atlantic salmon, and Icelandic populations of sea-run brown trout (*Salmo trutta*). This last example shows a marked increase in records over the smoothed observation period (1991–2007), and may be attributable to a true increase in population or an increase in sport fishing, or both (Gudbergsson 2007).

**Conservation status**

We believe the conservation status of anadromous fishes integrates knowledge of population persistence, abundance, and threats. Of the 12 exclusively North American species, the International Union for the Conservation of Nature (IUCN) Red List classifies 1 as endangered and 2 as vulnerable; the National Marine Fisheries Service lists 3 others as species of concern; and the ASMFC rates 1 more as having its lowest abundance in history, and is in the process of assessing 2 more species that are also likely at historic lows. Of the 9 eastern Atlantic species, 1 has gone extinct, 2 are now critically endangered (including the once abundant European eel), 1 is vulnerable, and 2 are listed by the IUCN as data deficient (table 1). At least one (*A. alosa*) appears to be in serious decline, although noted as “least concern” by the IUCN. Of the pan-Atlantic salmonids (Atlantic salmon and arctic char, *Salvelinus alpinus*), wild *S. salar* is at historic lows in North America, and overall, its status is in need of updating (IUCN 2008).

**Threats**

North Atlantic diadromous fishes must navigate a gauntlet of threats. The primary triad that affects most taxa is damming of rivers, overfishing, and pollution. However, there are now a host of threats beyond the three that have long been considered primary.

**Dams and other habitat losses.** Industrialization depended on rivers for water power, and many waterways became multiply dissected with dams. Dams often block access to historical spawning reaches, causing population reductions and extirpations. Few larger rivers remain undammed: It is estimated

---

**Figure 1.** Normalized time series of indices of abundance of selected north Atlantic diadromous species. European eel includes standard errors of means for nine regions. The lower two panels compare Atlantic salmon. For type of index, maxima, minima, percentage change, and data sources, see table 2. Unless otherwise stated, northwestern Atlantic data are US summary statistics.
that in the United States alone, there are more than 80,000 
dams of 6 feet in height or more, and perhaps as many as 
2,000,000 of all sizes (Graf 2003). For example, within the 
Hudson River watershed there are 797 registered dams 
(Swany et al. 2006); that figure does not include small dams 
(< 0.6 m tall), which also can hinder migration. In Spain, some 
dams have blocked fish movements continuously since the 2nd 
century, and the nations of Europe together have about 7000 
large (more than 15 m) dams, most of which are situated on 
Atlantic drainages. Engineered solutions to fish passage in 
the form of ladders and lifts have been fitted to some dams, but 
generally passage is species specific, and the number of fish 
traveling through them is far fewer than it would be in the 
absence of dams; these dams also inhibit downstream 
migration of young. One useful metric of the effect of 
dams is the number of kilometers of river they occlude to 
migrants. For American shad, approximately 4000 of an 
original 11,200 km of spawning habitat have been lost to 
dams (Limburg et al. 2003); these dams have similar effects on 
other anadromous species.

Dams also have numerous other ecological effects on rivers, 
many of which may affect diadromous fishes directly or 
indirectly. Among these are the blocking of normal movements 
and changes in the community composition of resident fishes 
that interact with diadromous fishes; microevolution of 
populations isolated by barriers; pronounced alterations of 
water temperatures upriver and downriver; retention of 
nutrients and sediments; and, even where fish passage is 
successful, the imposition of the need to cross sometimes large, 
unnatural stillwater habitats (Helfman 2007). Dams that are 
operated for hydropower also cause direct mortality (death 
by turbines) and may radically alter water discharges (Helf-
man 2007)—and hence, habitat availability (water or no 
water)—on daily or even hourly timescales.

In addition to the large habitat changes wrought by dams, 
dredging and channelization may cause short-term stresses 
while these activities occur and, more important, long-term 
diminution of habitat quality through the changes they 
create. Culverts impede fish movements by species such as river 
herring in smaller systems. Gravel and water removals reduce 
habitat in many waterways. Because many anadromous fishes 
use rivers as nurseries, reductions in the extent and quality of 
marshes and other shallow water habitats may lessen 
productivity and, therefore, recruitment.

**Overfishing.** Harvest has strongly compromised diadromous 
fish populations. Atlantic sturgeon were compromised at an 
extraordinary rate during the international caviar craze of the 
1890s (Secor and Waldman 1999); with continued fishing and 
their low intrinsic rate of increase, many populations have 
shown little subsequent recovery, despite greater protection. 
In the Delaware River, the chief US fishery for Atlantic 
sturgeon, landings in 1901 were only 6% of their 1889 peak 
of more than 2000 metric tons (Secor and Waldman 1999). 
Atlantic sturgeon remain so scarce in the Delaware that it is 
not known whether any reproduction still occurs there.

Overfishing is a major factor in the nearly complete demise of the 
one-widespread European sea sturgeon (Williot et al. 2002). Extirpations led to a range contraction to just the 
Gironde estuary in France, and even when fishing was halted 
there in 1982, the population continued to decline. Despite 
regulatory protection, accidental bycatch threatens sturgeons 
on both the American and European coasts.

Alewives were once so numerous in northeastern US rivers 
that they were likened to “passenger pigeons of the sea” (Bol-
ster 2006); their numbers have since plummeted, and several 
states have banned any takings. Runs in several large rivers 
from Maine to the Chesapeake Bay have declined by 99.9%; 
for example, at the Holyoke Dam on the Connecticut River, 
counts went from approximately 630,000 in 1985 to 21 in 2006. 
Bycatch at sea is one likely contributor, as subadults are taken 
along with the targeted Atlantic herring (*Clupea harengus*) fish-
eries. Another alosine that appears to be undergoing a simi-
lar collapse because of recruitment overfishing is the allis 
shad; juvenile recruitment in the Gironde, the center of its ange, has been negligible for the past few years.

Extensive analysis of decadal trends in eel fisheries suggests 
that exploitation is a major factor in European eel decline 
(Dekker 2004), with many fisheries collapsed. Eels are targeted 
not only as immature (yellow phase, in lakes and running 
waters) or adolescent (silver phase, migrating toward the 
Sargasso Sea to spawn) but also as postlarval glass eels entering 
continental waters. The highly lucrative glass eel fishery is
driven by demand in Southeast Asia, where imported American and European glass eels are pond-reared to market size. Glass eel fisheries sometimes harvest all available individuals at a particular locale, but in general the harvest has been 80% to 95% (Dekker 2004), which is still an alarming statistic.

Pollution. Water pollution also has reduced runs of diadromous fishes. Some river systems received so much raw or lightly treated human sewage—which became low oxygen levels—that they became equivalent to "chemical dams" blocking spawning migrations. Examples include the Thames in the United Kingdom and the Delaware River in the United States (Chittenden 1971); however, both rivers have shown dramatic improvements as a result of new laws and management actions. Over the past few decades, shortnose sturgeon has made an unusually robust recovery in the Hudson River not only because of its placement on the US endangered species list but also because the population's original spawning location near the head of tidewater was reoxygenated through measures to control sewage, which stemmed from the Clean Water Act of 1972 (Waldman 2006). However, late 20th-century exurbanization (sprawl development) has led to more impervious cover in many drainage basins, further altering water quantity and quality.

Contaminants such as polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons, and heavy metals may induce difficult-to-quantify sublethal effects in fishes in riverine environments. Highly biomagnified levels of PCBs in boreal regions are causing concerns for Arctic char. Laboratory experiments with Arctic char have shown that these compounds impair hypo-osmoregulatory ability and reduce growth rate and survival upon transfer to seawater (Jorgensen et al. 2004). Also, European and American eel reproduction may be compromised by fat-soluble, teratogenic organic compounds (Palstra et al. 2006), which are translocated into developing embryos from maternal lipid stores.

Acidification from atmospheric deposition of contaminants has been devastating for some Atlantic salmon stocks. In Norway, 18 populations are extirpated and 8 more are threatened, with others sustained only by liming rivers to raise pH (Sandoj and Langaker 2001).

Climate change. Climate change is altering species distributions. The boreal rainbow smelt Osmerus mordax, which in the 1880s ran in US rivers as far south as the Delaware, was extirpated from the Hudson in the 1990s (Waldman 2006) and is becoming scarce everywhere south of Maine. Meanwhile, gizzard shad (Dorosoma cepedianum), a euryhaline clupeid of no commercial value and uncertain ecological effects, has been colonizing rivers northward, establishing in large numbers in the Hudson in the 1970s and recently reaching as far as Maine (Waldman 2006).

Warming also appears to be shifting the phenologies of anadromous fishes towards earlier spawning runs. Monitoring in Maine revealed that the median capture date for Atlantic salmon in the Penobscot River advanced by 1.3 days per year between 1986 and 2001, and by 1.2 days per year between 1983 and 2001 for alewife in the Androscoggin River (Huntington et al. 2003). The consequences of such acceleration are unknown, but the rapidity of the change has the potential to disrupt these fishes’ established ecological relationships at various life history stages.

In the future, warming may intensify the severity of floods and droughts, lessening the frequency of successful annual reproduction for anadromous fishes. In Europe, models predict that, collectively, 22 species will lose 336 suitable catchments and gain only 113 as a result of the most likely climate change scenario (Lassalle and Rochard 2009). The Gulf sturgeon (Acipenser oxyrinchus desotoi) depends on limited numbers of cool thermal springs to survive hot summer temperatures in Gulf of Mexico rivers (Carr et al. 1996); warming may impose even greater stresses on this scarce and federally threatened subspecies.

Warming will also impose complex and difficult-to-forecast shifts in the relationships between freshwater and saltwater habitats. Both American and European eels have evolved to capitalize on the transport and trophic resources of the Gulf Stream. However, the recent effects of climate change on this current may be contributing to the declines seen in both eel species in freshwater (With and Bernatchez 2003). In Arctic regions, warming may increase the productivity of inshore marine habitats used by anadromous fishes, but this may be counterbalanced by decreased flows in spawning rivers. Increased productivity of inland waters may also reduce facultative anadromy for plastic species such as Arctic char, with higher proportions of populations opting for freshwater residency (Reist et al. 2006).

Other threats

Electric generating plants and other facilities that withdraw water from rivers may kill high numbers of early life stages of diadromous fishes through entrainment and by impinging larger individuals against intake screens; power plants may also alter local temperature regimes though discharges of warm water (Barnthouse et al. 1988). Disease, competition, and genetic introgression with escapees from aquacultured Atlantic salmon threaten wild stocks in northeastern North America and Scandinavia (Naylor et al. 2005). Progeny of Atlantic sturgeon used in experimental culture have been opportunistically stocked in the wild (St. Pierre 1999) while ignoring protocols for the maintenance of appropriate effective population sizes. Similarly, research-culture escapees of a nonnative sturgeon species now compete in the Gironde with the few remaining sea sturgeon (Maury-Brachet and Rochard 2008). Many invasive and nonnative species also disrupt lotic ecology. Introduction of black bass (Micropterus spp.) and other piscivores increased the predation regime for juvenile alosines and other young diadromous fishes in US rivers. Invasive zebra mussels (Dreissena polymorpha) have altered the Hudson River’s spring production cycle, to the detriment of its alosines (Strayer et al. 2004).
Conclusions
Few of the North Atlantic’s diadromous fishes face any of the abovementioned threats in isolation; rather, it is likely that reasons for the losses we have outlined are multifactorial, and possibly synergistic. Many of these declines have been steady and insidious, fitting well into the “shifting baselines” paradigm, whereby new generations of managers accept that recent environmental conditions and levels of species reflect historical conditions and levels, and set restoration goals accordingly (Humphries and Winemiller 2008, Waldman 2008). Loss of historical baselines contributes to marginalization of the species, as social customs relating to bygone (collapsed) fisheries also perish, and ecosystems unravel at rates that go unnoticed.

Especially troublesome is the outright loss of many populations and their genetic legacies in the face of changing environments. The high phylogenetic diversity of these 24 species and the differences in life histories, geographic ranges, and commercial values conspire to make generalized solutions impossible. There is a strong need for better information on the population-specific status of many species of low commercial interest. Harvests of some species have been reduced and moratoria have even been applied, but usually not until abundances had become dangerously low. Atlantic coast populations of migratory striped bass are one of the few successful recoveries for an anadromous species, but the severe measures needed to generate this recovery were not taken until the stock fell to crisis levels (Richards and Rago 1999). Even with moratoria, populations may fail to recover (e.g., A. sturio in the Gironde, A. sapidissima in Chesapeake Bay), suggesting changes occurring systemwide are collectively hindering recovery.

Fishermen and other stakeholders need to elevate their long-term interests in a species’ welfare over their own short-term economic interests, with the understanding that the more the populations are fished, the less the likelihood of recovery (and the lengthier the period of recovery), and hence the more damage to the future sustainability of the fishery. A laudatory example of an early intervention is the moratorium imposed in late 1997 on Atlantic sturgeon fishing in US waters in response to indications that some populations were rapidly declining because of suddenly increased fishing pressure (Waldman 2006). Almost exactly a century after the international caviar craze left many US stocks sharply reduced or decimated, the few remaining commercial Atlantic sturgeon fishermen acquiesced to an ambitious protection plan that prohibits their take for up to 40 years—two generations for this slowly maturing species.

The environmental movement has resulted in a reduction of new sources of pollution in the United States and Europe, but many rivers still have a legacy of contaminants produced from the Industrial Revolution through the mid-1900s. Although cleanup actions have been helpful for some species in some places, the single broadest and most useful recovery action has been to remove dams wherever possible. This is especially true for large mainstem dams. For example, when the Edwards Dam on Maine’s Kennebec River was removed in 1999, the benefits to the full suite of this river’s diadromous fishes were almost immediately visible as the fishes reoccupied their historical spawning grounds. Where dams cannot be removed, it is far preferable to install fish passage devices, despite their flaws, than to impede the movements of all diadromous fishes in a river. Research to enable passage of anadromous species that shun conventional fish ladders, such as sturgeons, should also be encouraged.

Viewed collectively, North Atlantic diadromous species underwent similar sequences of events that led to their declines (figure 3). Although quantitative data are largely lacking, anecdotal evidence from diaries, journals, and other historical accounts suggests that pristine populations of diadromous fishes were staggering in their plenitude (Waldman 2008), and formed the basis of important fisheries. Gradually, some populations became extirpated, but the pace of extirpations through the mid-20th century was slow enough to forestall great alarm (but note that overfishing of American shad in the 19th century spurred concerted management efforts).

The cumulative impacts resulted in declines, but these declines in themselves have had another unintended consequence: namely, a loss of standing or “saliency” among issues considered important by society at large. As species became scarce, fisheries declined, and often demand dropped off. Other watershed uses gained prominence. As demand dwindles and constituencies are lost, it becomes increasingly difficult to motivate and secure funding for adequate management and restoration measures. This downward spiral of...
events lacks a term, but we suggest that it is a kind of ecosocial anomie, a breakdown both of expectations of what species should be present in healthy populations, and societal loss of interest. The result is not only the loss of populations and species but also the loss of services the species provided when their inland ecosystems were more intact.

The stories of individual stocks that perished or are commercially extinct are numerous, but it is clear that the diminishment of diadromous fishes, taken as a group, represents one of the greatest corruptions of the ecological connections between North American and European watersheds and the North Atlantic ecosystem. Although management needs to consider the specifics of each species and population, the causes of decline we have outlined appear to be general and widespread. If there is to be a future for this group, societies must make difficult decisions concerning the trade-offs between maintaining healthy populations within healthy ecosystems and taking actions that degrade and imperil those systems. The emerging field of ecosystem service quantification may provide ways to enhance restoration, since it highlights those services that depend on ecosystem function as well as provisioning services. If ecosystem service quantification becomes mainstreamed (Cowling et al. 2008), local and regional decisionmaking would have an alternative to conventional cost-benefit schemes. These alternatives would support ecosystem and habitat restoration. It may take decades to bring back diadromous species, but restoring the watersheds and their connectivity with coastal marine ecosystems is a critical first step in that direction.

Acknowledgments
We thank Miran Aprahamian and Willem Dekker for providing data sets; Eric Rochard and Géraldine Lassalle for discussions and suggestions; and Miran Aprahamian, Charles Hall, George Jackman, Aude Lochet, Michael Pace, Carl Safina, Dennis Suszkowski, and two anonymous referees for helpful comments on earlier drafts. This project was supported in part by a Fulbright fellowship and the National Science Foundation (DEB-0238121).
